1 Introduction

For our term project in CAS 703 [1], we decided to build a language for describing calculation schemes. The descriptions should be mostly understandable to anyone who has worked with Excel [2] or has used any kind of calculation software. We aim to validate the coherence¹ of the calculator descriptions. Additionally, through generative techniques, we hope to decrease the barrier to entry (as much as we can) of basic software development of calculator programs by defining a transformation of the calculator descriptions to various programming languages².

1.1 Objective

We aim to:

1. design a metamodel for describing calculator programs (Section 2),
2. build a concrete syntax for the metamodel, and an Integrated Development Environment (IDE) for said concrete syntax (Section 3),
3. design a set of rules that define “coherence” rules of the metamodel and audit instances of the metamodel for coherence (Section 4), and
4. define a transformer that converts the calculator description into programs and corresponding documentation (Section 5).

1.2 Tooling

We will use the tooling shown in 703, namely: Eclipse Epsilon [3] and the languages it contains, and Xtext [4].

¹“Coherence” defined by an unambiguous set of constraints and rules.

²Notably, Java programs.

2 Modelling

To define our metamodel for our desired Domain-Specific Language (DSL), we first need to iron out the *requirements* of that language.

2.1 Requirements

When we (the authors) think of “calculators,” we think of 3 main components: (i) a set of input symbols, (ii) a set of output symbols, and (iii) a means of deriving the output symbols from the input symbols. (i) and (ii) are really just “symbols” with designation of whether they are user-provided or calculated. (iii) is a (commonly secret) algorithm that translates (i) to (ii) and which may rely on intermediate symbols irrelevant to (i) and (ii). Thus, we think of a calculator as being a structure of (a) symbols of different kinds (inputs, intermediates, and outputs) and (b) an algorithm that calculates some symbols from an initial subset of provided symbols.

Depending on your preferred school of thought, algorithms can be thought of differently. We choose to think of them as being similar to imperative-style programming languages, where there is a memory of symbols to values, and a sequence of steps/statements that are executed sequentially against the memory.

The most important kind of “step” our algorithm must have is “symbol assignment,” where some symbol is assigned the value of some expression. The expression may contain other symbols, but it should be restricted to only using symbols that have been assigned values (either as input to the calculator or by an earlier step). Logging is another important kind of step that algorithms might need, they’re typically used for providing user-feedback for debugging, general information, warnings, errors, etc. Logging, similar to assignment steps, are provided an expression, for which are evaluated, but the difference is that the logging step displays the value to the user-feedback mechanism of the calculator rather than assigning the value to a symbol. For now, we choose to think of calculators as only having these 2 kinds of steps.

The steps rely on a single mathematical expression language that describes how values can be altered in a predictable way. We choose to restrict our expression language to the common first-order definite-valued mathematical language that most undergraduates in a first-year university mathematics class are familiar with.

Similar to how we expect our expression language to provide predictable results, we also expect our calculators to be predictable and reliably produce accurate results. To gain confidence in accuracy and predictability, we can test our calculators against well-known outputs for well-known inputs. In other words, we can create test cases to gain confidence that our calculator is reliable (which we want to reasonably assure ourselves).

Thus, together, we define our calculator as having 3 main aspects: (a) a set of symbols, (b) an algorithm that somehow calculates the output symbols from the inputs, and (c) a set of test cases to gain confidence that (b) is reliable. To model our calculator DSL, we chose to use Emfatic (EMF) because we found it to be faster to work with. In particular, we found it to be more readable and easier to modify compared to Ecore.

2.2 Emfatic

Listing 1: Calculator EMF

```
class Calculator extends Described {  
    attr String[1] name = "";  
    val SymbolDeclaration[*] symbolDeclarations;  
    val CalculationStep[*] steps;  
    val TestCase[*] testCases;
```

}

When translating the calculators to Emfatic (Listing 1), we also added the name and a description of the calculators using string attributes³. The calculator class contains 3 other “containment references” (vals): symbol declarations, calculation steps (denoting the algorithm), and a set of test cases.

Symbol declarations (`SymbolDeclaration`, Listing 3) define a symbol (`Symbol`) with a textual description and the *kind* of symbol it is — input (user-provided at the start of the calculator), intermediate (derived from the inputs but not important), or output symbols (symbols that users are interested in calculating). Since the difference between the symbol kinds is quite surface level (or so we claim), we chose to use an `enum` attribute in our symbol declaration type. If there were any behavioural differences, we would have used a subclass. The symbol content itself is contained in another class (`Symbol`) with a one-to-one relationship with symbol declarations. `Symbols` contain a name attribute (assumed to be a Java-friendly identifier) and a declared *type* of the symbol. The types are containment references of `Types` (Listing 6).

We chose to build a basic unambiguous, static, judgment-based [5] type system. We restricted our type universe in our calculator to “simple” first-order types with no parameters. Thus, we have booleans, strings, integers, and real numbers. However, we do intend to implement vectors as well. We used an abstract `Type` class to create a generic class of types (with basic feature requirements), and then a subclass (`PrimitiveType`) to designate primitive types using an enumeration of primitive types (`Primitive`). By extending the basic `Type` class with other types, we can further extend our DSLs type system.

The next major component of our calculators are the calculation steps. As already mentioned in Section 2.1, we restricted ourselves to 2 kinds of steps: assignment steps, and print steps. Assignment steps (`AssignmentStep`) and print steps (`PrintStep`) are both subclasses of the abstract base class: `CalculationStep` (Listing 4). Print steps contain a description (we called it a “preface”) for the need to print a particular symbol (noted by reference). `AssignmentSteps` contain a reference to a symbol, an optional description `String` attribute, and a value reference to a defining expression. The expression is expected to be well-typed, but we only impose this restriction in Section 4.

Expressions have a shared base class: `Expression` (Listing 7). There are various kinds of expressions we’ve implemented, such as literals (`TextLiteral`, `BooleanLiteral`, `IntegerLiteral`, `RealLiteral`), symbol references (`SymbolExpression`), unary expressions (`UnaryExpression`), binary expressions (`BinaryExpression`), and tertiary expressions (`TertiaryExpression`). The `Expression` abstract base class defines a basic functionality set that each subclass of expression must provide — namely printing, type inference, symbols it depends on, and a Java representation method.

The last component of our calculators are test cases. We expect that instances of these calculators to obey a set of test cases. Our `TestCase` class is defined with a name and description `String` attributes, a list of assignment steps (that are expected to reference no symbols in their expressions), and a list of boolean-typed expressions⁴.

Finally, these 3 important classes define our calculators, and we may continue to our next project: building a concrete syntax for our DSL.

³Note that since we commonly use comments and descriptions, we added a “Described” base class to quickly attach description attributes (Listing 2).

⁴Both restrictions are only imposed in Section 4.

3 Integrated Development Environment

We decided to use Xtext to build our IDE because the nature of our program usage is not graphical, it is very mathematical, and so we felt text was best. At first, we developed an IDE using Xtext that worked fine, but it was not connected to our metamodel. Then we struggled to connect it to our metamodel, and so we had to restart our Xtext project, basing it on our “metamodel.genmodel” file. The concrete syntax looks like Figure 1, and the full concrete syntax is in the appendix.

```
1 calculator potato "hello this is a general purpose calculator"
2 symbols
3 OUTPUT x : REAL ~ "distance from origin"
4 INPUT v : INTEGER ~ "speed"
5 INPUT a : REAL ~ "acceleration when stopping"
6 OUTPUT log : TEXT
7 OUTPUT isPositive : BOOLEAN
8 INTERMEDIATE stopTime : REAL
9 INPUT t : INTEGER ~ "time passed"
10 steps
11 x = (* v t) ~ "calculate distance"
12 isPositive = (> x 0) ~ "isPositive will be true if value of x is greater than zero"
13 log = "OK"
14 stopTime = (/ v a)
15 print(log, "this is optional") ~ "comment"
16 testCases potatoTester for "just for test"
17 inputs
18 v = 4
19 a = 2
20 t = 2.5
21 assertions
22 (== x 4)
23 [|> stopTime 3|]
```

Figure 1: A simple example of our calculator in our IDE

Design Decisions:

1. Connecting Xtext to our metamodel forced us to do some modifications in our pre-existing syntax. One of this changes for the symbol kind. In the symbol declaration section, each symbol should be associated to one of three kinds (INPUT, INTERMEDIATE, OUTPUT). Our first choice was to have three subsections (one for each kind), and every symbol should be defined in the corresponding subsection⁵. However, after connecting Xtext to our metamodel, we were not able to do that because we had to set a default value for `SymbolDeclarationKind` attribute in `SymbolDeclaration` class and Xtext does not allow us to assign information without consuming some sort of text (which we didn’t want to have) even though our grammar was still context-free. Now, all symbols are defined in one “symbols” section with their kind manually specified for each of them. See lines 2-9 in Figure 1 for example, we originally wanted the kinds of symbols to be separated into blocks of symbols.
2. One other modification we had to make for the same problem with enums was for expressions. In the first xtext project(the one that was not connected to metamodel) we implemented expressions very well. Precedence of every expression was considered. We tried to do the same thing here (xtext connected to metamodel) but it was not possible

⁵For example, a section for input variables, intermediate variables, and output variables.

since we were not able to assign a default value to the operation attribute(which is an enum). Therefore, we decided to change the syntax for expressions to s-expressions.

Beside the rules that are defined in the grammar, we defined three validation rules in our IDE. Checking these rules was not possible without adding special validation rules to Xtext. If users don't follow these rules, they will see a corresponding error (see Figure 2 for example).

```

All Input variables should be assigned at least once in testcase
section!
OUTPUT x : REAL ~ "distance from origin"
INPUT v : INTEGER ~ "speed"
INPUT a : REAL ~ "acceleration when stopping"
OUTPUT log : TEXT
OUTPUT isPositive : BOOLEAN
INTERMEDIATE stopTime : REAL
INPUT t : INTEGER ~ "time passed"
steps
x = (* v t) ~ "calculate distance"
isPositive = (> x 0) ~ "isPositive will be true if value of x is greater than zero"
log = "OK"
stopTime = (/ v a)
print(log, "this is optional") ~ "comment"
testCases potatoTester for "just for test" calculator
inputs
v = 4
a = 2
assertions
(== x 4)
[> stopTime 3]

```

Figure 2: Validation error in our IDE

Validation Rules incorporated in our IDE:

1. Every symbol must have a unique name.
2. Every symbol with output or intermediate kind must be assigned at least once in the steps section.
3. Output and intermediate symbols should not be assigned in test case section.
4. Every input symbol must be assigned a value in test case section.
5. Using any symbol's name in steps or test case section that is not already defined is not allowed.

Unfortunately, as we had left our IDE development to our last step in our DSL development, not all of our validation rules appear in our IDE. However, we do hope to integrate them soon in full.

4 Model Validation

Using the Epsilon Validation Language (EVL), we built a series of constraints to impose restrictions we weren't able to adequately impose through the metamodel (Listing 8). In particular, we built a series of constraints (hard requirements) and critiques (soft requirements/preferences) for models of our metamodel.

Calculator Constraints:

1. *named*: each calculator must have a name for users to disambiguate between calculators and their other files,
2. *unique symbols*: each calculator must have a set of symbols that have unique names within that set so variable references can be unambiguous,
3. *at least 1 input*: each calculator should have at least 1 input symbol or else there is no interactivity with the calculators generated, so a normal calculator should be used instead,
4. *at least 1 output*: each calculator should have at least 1 output symbol or else there would be no way to audit or use the calculator,
5. *all outputs assigned once*: all designated output symbols are meaningful in some way and should be guaranteed to have a value at the end of the calculation steps,
6. *all intermediate symbols assigned once*: if a declared intermediate symbol is never assigned, then it can be removed to de-clutter the calculator,
7. *all assignment steps well-typed*: each assignment should involve a symbol of the same type as an expression,
8. *all test case assignments are input symbols*: the pre-calculation state of the calculators should only have input variables assigned values,
9. *all test case assignments contain no variable references*: all assignment bodies in test cases should be evaluable to literal-valued expressions (e.g., contain no symbol references) because there is no defined variables before input set,
10. *all test cases assign all input variables*: each test case should mimic users fully, by providing all necessary inputs the calculator would need,
11. *all test case inputs unambiguous/“no duplicates”*: each defined test case should have no ambiguous symbol assignments or else the initial state of the test case simulations would be ambiguous,
12. *all test case assertions are boolean-typed*: the assertions should be propositional statements or else they should be part of the calculation steps of the main calculator,
13. *all steps depend on non-null symbols*: each step of the calculation should only rely on symbols with defined values or else invalid and undefined expressions and operations will occur, and
14. *all test cases satisfied*: the calculation steps should be simulated under each test case, and each test case should be satisfied.

Calculator Critiques:

1. *description*: it would be nice to have a description of the intent of the calculator and general information about how it works,
2. *all inputs described*: it would be nice for each input symbol to have a user-friendly description to describe what the variable means,
3. *all outputs described*: same as above, and
4. *all test case assertions meaningful*: each test case assertion statement should reference symbols in that calculator or else the assertion would be evaluable without simulation.

Symbol constraints:

1. *named*: each symbol should have a name or else using them would be impossible, and
2. *named with only appropriate characters*: a restriction imposed by desiring Java-compilation and non-unicode data entry — names/identifiers should be usable as Java identifiers.

Finally, we have our last constraint: each expression should be well-typed, or else invalid states are possible, and we don’t want calculators to ever get “stuck.”

Together, these make up our constraints. We build them using standard EVL tooling (Listing 8) and run them using a Gradle script on our parsed model. If all constraints and critiques are satisfied for a model, then we claim that the produced artifacts (see Section 5) and the model are relatively high-quality. Furthermore, we claim that the produced code artifact should be well-typed, and thus never run into invalid states, errors, or any issue at runtime (excluding that related to business logic).

The simulation of the test cases is one of our larger validation schemes. We had to emulate the Java code that would be run under the test cases provided. Unfortunately, we were not able to add an “evaluation” method to the base `Expression` class because we needed the return type of the function to be `Any`. We wanted to use `Any` because we wanted to use the dynamic typing nature of EOL to avoid model duplication for literal values. However, the EMF language does not support `Any`, and thus we had to “attach” this functionality post-facto in our shared “program.eol” file used by all of our other files. For simulating the calculation steps, we faced similar issues with our base `TestCase` type. We had to have an implicitly known base property of test cases that they are simulatable. For expressions, our evaluation methods were given an (implicitly) read-only “scope” Map for them to reference symbols. Similarly, for our simulation, we also had to pass along the current variable state of the simulation memory. However, the calculation steps are allowed to read from and modify the scope. The full code for simulation works by populating an initial memory state with the input variables, executing the calculation steps on the memory, and then checking that all the provided assertion propositions hold true (Listing 9, specifically the `isSatisfied` operation).

Another notable constraint is the dependency-checking of each calculation step — that is, each step should only rely on symbols that are reasonably guaranteed⁶ to have been assigned a value already. In order to validate, we had to iterate over the calculation steps sequentially, processing what impact they would have on symbols and what symbols they rely on to decide whether they are okay or not (Listing 10). The initial set of valid usable symbols are only the input symbols, and it is expected that by the end, each output symbol is calculated. The remainder of the validation rules rely on asserting propositions over all instances of data types, mostly with respect to a particular calculator, using the standard primitive tooling available in EOL and EVL. Finally, with the validated models, we may build our desired artifacts.

⁶“Division by 0,” and other issues that would require a dependent type system to mitigate are not considered.

5 Model Management Operations

As mentioned in Section 1.1, our final objective is to realize the calculator models into vetted, usable programs for end users. Ultimately, our goal is that the program should be simple enough that any computer user may be able to use the generated programs. However, this requirement requires a lot more work to assure user-friendliness across audiences, portability across various operating systems, and may involve a Graphical User Interface (GUI) or other modes of computer interaction. Thus, for the time being, we restrict ourselves to building Command-Line Interface (CLI) tools using a programming language that is already sufficiently portable (i.e., Java⁷). Additionally, to complement the CLI calculator tools we generate, we also generate a “read me” file in Markdown (i.e., a `README.md` file). To generate both artifacts, we used 2 Epsilon Generation Language (EGL) files alongside the EGL Co-Ordination Language (EGX) to orchestrate their usage.

5.1 Working with EGL

Working with EGL was quite enjoyable for us, we found little to no issues at all using it. We chose to treat the target artifacts as “text” (hence using EGL) rather than “models” (which would require encoding Markdown and Java models) due to time constraints on the course and complexity associated with building a full Java Abstract Syntax Tree (AST) in EMF. Thus, we performed model-to-text model transformations. We built some extra tools in EOL to simplify our EGL code, such as adding defaults for empty strings, expression conversion to human-readable syntax, grabbing only the input/intermediate/output symbols, and more. One difficulty faced is generating the human-readable expressions without excessive parentheses. Ultimately, this was a constraint by time rather than by knowledge or the Epsilon tools since we wanted to have a custom mathematic notation for the end users of the programs. In other words, the human-readable notation would be appear slightly different than the input calculator models. However, it would have the same meaning and behaviour (and a bijection would exist between them).

We fed in calculator instances to each of the EGL files and used that calculator instance to grab all necessary information to generate each file (Java or Markdown, respectively). The majority of the code involved (a) accessing variables from the model, (b) pretty-printing the variables in-place as necessary, and (c) adding default information and explanatory text where applicable (such as when the model contains no intermediate symbols and we want the user to know).

5.2 Generating a Java Program

To generate our Java CLI programs, we built an EGL file (Listing 12) and hooked it up to our EGX (Listing 11) to make sure we have a special folder to carry our Java programs, one for each defined calculator. First, we manually built a prototype calculator of what we wanted to build, and then we gutted out the internal components that are accustomed to the model⁸ and regenerated them using the input models. We used the Java standard library for scanning the console for inputs from the user (via `Scanner` usage on `System.in`), printing (via `System.out.println`), and certain non-standard calculations (via `java.lang.Math`, such as `Math.pow` for powers). We setup the code to create a basic introductory message and then immediately prompt users for the inputs

⁷Note that this requirement of Java required us to slightly adjust our typing rules with generating Java code in mind! For example, until we build our own standard library tooling, we weren’t able to have integer exponentiation since the `java.lang.Math` package does not support integer powers without casting.

⁸In other words, we abstracted over the data that was obtained from the model.

(in the order they are defined in the model). Afterwards, the code will define the intermediate and output symbols, and run through the calculation steps sequentially⁹. Finally, we print the value of each defined output symbol at the end of the program, and it terminates. The program is a single-file source program, so usage only requires a single `java Main.java` execution in your preferred shell. Hopefully in the future we will be able to make this usage and interaction with the CLI programs more user-friendly.

5.3 Generating a README File

Similar to our Java program generator, we also built an EGL file (Listing 13) and hooked it up to our EGX (Listing 11) to make sure we have a special folder to carry our Java program along with the README files, specialized to each defined calculator in the model. Again, we built a prototype README file and abstracted over the details specialized to models. For example, we created variables for the names, descriptions, input, intermediate, and output symbol tables, calculation steps, and test case descriptions. Afterwards, we regenerated the `README.md` files using our EGL code. We made sure to include documentation for the usage of the Java programs¹⁰, a description of all the relevant variables to the program, a description of the calculation steps the program takes, and the list of test cases that were used to assert that the calculator models are reasonably well-behaved.

Additionally, in both the Java program and the README files, we added some basic accreditation information, noting that the software was built for educational purposes under Dr. Richard Paige’s offering of CAS 703 at McMaster University [1].

⁹In the future, we may be able to look to parallelization and concurrency for large calculators.

¹⁰With a target audience of users comfortable with the command-line, such as Junior Programmers and Data Analysts.

6 Reflection and Concluding Thoughts

Ultimately, we greatly enjoyed working on this term project. Working with Eclipse and Epsilon tooling was very enjoyable. The documentation for all Epsilon tools was stellar, and the Epsilon Playground allowed us to play around with the micro-models in isolated situations.

We only found light, noticeable issues with `enum` support across tools, and with Xtext usage. Specifically, `enums` are not usable as parameter types in operations in EOL, but are in EMF. The flexibility allowed by the Epsilon tools was great, but the consistency here was problematic. Similarly, in Xtext, enumeration values could not be defaulted for constructions, which lead us to making an unfortunate decision to annotate our symbol declarations with excessive “input,” “intermediate,” and “output” keywords (one per) for each declared symbol. Originally, we only wanted to have a grouping of them where each block of symbols was contained in one of those keyword blocks and assigned the related `enum` value for the declaration kind. Additionally, with Xtext, we found difficulty in debugging issues related to our grammar and ended up needing to implement S-expressions for our mathematical expression language so ease the issues and assure that we could deliver for the deadline. We are confident that with more time, we would be able to the appropriate mathematical expression language for the concrete syntax, but for now, we are left with this.

On the side of Epsilon tooling, we found great enjoyment working with Gradle and Ant to orchestrate the compiler. Originally, we developed an input model using Flexmi and used that to drive development against calculators, and then we worked towards adding Xtext to build a concrete syntax for our language. We still preferred to keep the textual concrete syntax because a graphical language we thought that defining expressions would be too time intensive for users.

In the future, we hope to (at least):

1. further integrate our Gradle build script components with our Xtext-based editor,
2. add extra support for vectors and more operations in our metamodel and concrete syntax, and
3. generate more kinds of software artifacts (such as GUI-oriented programs, a single program that can connect multiple calculators, and interactive web-based Single Page Applications [SPAs]).

Model-driven engineering, the underlying theory, and practical applications thereof it, have been wonderful to learn about, and we hope to use these tools and ideas in the future.

## Software Guide

### Software Prerequisites

You should make sure to have a working installation of a Java compiler on your
system. This guide will assume you are using one of the standard Java tooling,
such as OpenJDK.

### Running the Calculator

The calculator is the standalone 'Main.java' file that is provided. To run it,
you should only need to run 'java Main.java' in your shell. If you prefer to
compile it into a Jar or a class file first, you should follow the instructions
provided by your installed Java development toolkit.

## Symbols

The [Inputs](#inputs) and [Outputs](#outputs) tables show variables relevant to
user interaction and usage of the [%=c.name%] calculator. The [Intermediates](#intermediates)
table shows variables strictly relevant to the underlying algorithm used for
deriving the outputs from the inputs.

### Inputs
[%var inputs = c.inputs();%]

[%if (inputs.size() == 0) {%]
There are no input symbols.
[%} else {%]
| Symbol | Description | Type |
|:-----|:-----|:-----|
[% for (s in inputs) {%]
| [%=s.name%] | [%=s.declaration.description.withDefault-("")%] | [%=s.type.serialize()%] |
[% }%]
[%}%]

### Intermediates
[%var intermediates = c.intermediates();%]

```

```

[%if (intermediates.size() == 0) {%]
There are no intermediate symbols.
[%} else {%]
| Symbol | Description | Type |
|:-----|:-----|:-----|
[% for (s in intermediates) {%]
| [%=s.name%] | [%=s.declaration.description.withDefault-("")%] | [%=s.type.serialize()%] |
[% }%]
[%}%]

### Outputs
[%var outputs = c.outputs();%]

[%if (outputs.size() == 0) {%]
There are no output symbols.
[%} else {%]
| Symbol | Description | Type |
|:-----|:-----|:-----|
[% for (s in outputs) {%]
| [%=s.name%] | [%=s.declaration.description.withDefault-("")%] | [%=s.type.serialize()%] |
[% }%]
[%}%]

## Calculation Steps
[%var steps = c.steps;%]

[%if (steps.size() == 0) {%]
There are no calculation steps;
[%} else {
    var sn = 0;
    for (step in steps) {
        sn += 1;%]
[%=sn%]. [%=step.toHRN()%]
    [%}
}%]

## Test Cases
[%var testCases = c.testCases;%]

[%if (testCases.size() == 0) {%]
There are no test cases.
[%} else {%]
The algorithm was tested in a simulation against the below test cases.
[% var curTC = 1;
    for (tc in testCases) {%]

### Test [%=curTC%]: [%=tc.name%]
    [%if (tc.description.length() > 0) {%]
*[%=tc.description%]*
    [%}%]

**Inputs**:
    [%for (input in tc.assignments) {%]
* [%=input.toHRN()%]
    [%}%]

**Assertions**:
    [%for (assertion in tc.assertions) {%]
* [%=assertion.toHRN()%]
    [%}%]

```

```
        [%curTC += 1;
    }%]
[%}%]
```
